Objectives

- Delve into the details of file systems and their implementation
- Explore booting and file sharing
- Describe remote file systems, using NFS as an example

File System

- General-purpose computers can have multiple storage devices
 - Devices can be sliced into partitions, which hold volumes
 - Volumes can span multiple partitions
 - Each volume usually formatted into a file system
 - # of file systems varies, typically dozens available to choose from

Example Mount Points and File Systems - Solaris

ufs /devices devfs /dev dev /system/contract ctfs /proc proc /etc/mnttab mntfs /etc/svc/volatile tmpfs /system/object obifs /lib/libc.so.1 lofs /dev/fd fd /var ufs /tmp tmpfs /var/run tmpfs /opt ufs /zpbge zfs /zpbge/backup zfs /export/home zfs /var/mail zfs /var/spool/mqueue zfs /zpbg zfs /zpbg/zones zfs

Partitions and Mounting

- Partition can be a volume containing a file system ("cooked") or raw – just a sequence of blocks with no file system
- Boot block can point to boot volume or boot loader set of blocks that contain enough code to know how to load the kernel from the file system
 - · Or a boot management program for multi-os booting
- Root partition contains the OS, other partitions can hold other OSes, other file systems, or be raw
 - Mounted at boot time
 - Other partitions can mount automatically or manually on mount points – location at which they can be accessed
- At mount time, file system consistency checked
 - · Is all metadata correct?
 - If not, fix it, try again
 - If yes, add to mount table, allow access

15.6

File Sharing

- Allows multiple users / systems access to the same files
- Permissions / protection must be implemented and accurate
 - Most systems provide concepts of owner, group member
 - Must have a way to apply these between systems

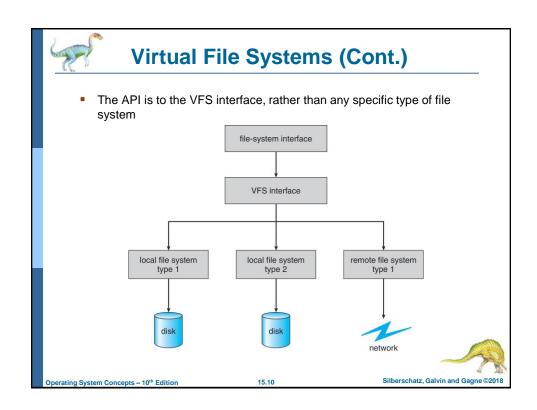

Virtual File Systems

- Virtual File Systems (VFS) on Unix provide an object-oriented way of implementing file systems
- VFS allows the same system call interface (the API) to be used for different types of file systems
 - Separates file-system generic operations from implementation details
 - Implementation can be one of many file systems types, or network file system
 - Implements vnodes which hold inodes or network file details
 - Then dispatches operation to appropriate file system implementation routines

Virtual File System Implementation

- For example, Linux has four object types:
 - · inode, file, superblock, dentry
- VFS defines set of operations on the objects that must be implemented
 - Every object has a pointer to a function table
 - Function table has addresses of routines to implement that function on that object
 - For example:
 - int open(. . .)—Open a file
 - int close (. . .)—Close an already-open file
 - ssize t read(. . .)—Read from a file
 - ssize t write(. . .)—Write to a file
 - int mmap(. . .)—Memory-map a file

Remote File Systems

- Sharing of files across a network
- First method involved manually sharing each file programs like ftp
- Second method uses a distributed file system (DFS)
 - · Remote directories visible from local machine
- Third method World Wide Web
 - · A bit of a revision to first method
 - Use browser to locate file/files and download /upload
 - Anonymous access doesn't require authentication

15.1

Client-Server Model

- Sharing between a server (providing access to a file system via a network protocol) and a client (using the protocol to access the remote file system)
- Identifying each other via network ID can be spoofed, encryption can be performance expensive
- NFS an example
 - User auth info on clients and servers must match (UserIDs for example)
 - Remote file system mounted, file operations sent on behalf of user across network to server
 - Server checks permissions, file handle returned
 - Handle used for reads and writes until file closed

Distributed Information Systems

- Aka distributed naming services, provide unified access to info needed for remote computing
- Domain name system (DNS) provides host-name-to-network-address translations for the Internet
- Others like network information service (NIS) provide user-name, password, userID, group information
- Microsoft's common Internet file system (CIFS) network info used with user auth to create network logins that server uses to allow to deny access
 - Active directory distributed naming service
 - Kerberos-derived network authentication protocol
- Industry moving toward lightweight directory-access protocol (LDAP) as secure distributed naming mechanism

Consistency Semantics

- Important criteria for evaluating file sharing-file systems
- Specify how multiple users are to access shared file simultaneously
 - · When modifications of data will be observed by other users
 - Directly related to process synchronization algorithms, but atomicity across a network has high overhead (see Andrew File System)
- The series of accesses between file open and closed called file session
- UNIX semantics
 - Writes to open file immediately visible to others with file open
 - One mode of sharing allows users to share pointer to current I/O location in file
 - Single physical image, accessed exclusively, contention causes process delays
- Session semantics (Andrew file system (OpenAFS))
 - · Writes to open file not visible during session, only at close
 - Can be several copies, each changed independently

The Sun Network File System (NFS)

- An implementation and a specification of a software system for accessing remote files across LANs (or WANs)
- The implementation originally part of SunOS operating system, now industry standard / very common
- Can use unreliable datagram protocol (UDP/IP) or TCP/IP, over Ethernet or other network

Operating System Concepts – 10th Edition

15.1

NFS (Cont.)

- Interconnected workstations viewed as a set of independent machines with independent file systems, which allows sharing among these file systems in a transparent manner
 - A remote directory is mounted over a local file system directory
 - The mounted directory looks like an integral subtree of the local file system, replacing the subtree descending from the local directory
 - Specification of the remote directory for the mount operation is nontransparent; the host name of the remote directory has to be provided
 - Files in the remote directory can then be accessed in a transparent manner
 - Subject to access-rights accreditation, potentially any file system (or directory within a file system), can be mounted remotely on top of any local directory

NFS (Cont.)

- NFS is designed to operate in a heterogeneous environment of different machines, operating systems, and network architectures; the NFS specifications independent of these media
- This independence is achieved through the use of RPC primitives built on top of an External Data Representation (XDR) protocol used between two implementation-independent interfaces
- The NFS specification distinguishes between the services provided by a mount mechanism and the actual remote-file-access services

Operating System Concepts – 10th Edition

15 1

NFS Mount Protocol

- Establishes initial logical connection between server and client
- Mount operation includes name of remote directory to be mounted and name of server machine storing it
 - Mount request is mapped to corresponding RPC and forwarded to mount server running on server machine
 - Export list specifies local file systems that server exports for mounting, along with names of machines that are permitted to mount them
- Following a mount request that conforms to its export list, the server returns a file handle—a key for further accesses
- File handle a file-system identifier, and an inode number to identify the mounted directory within the exported file system
- The mount operation changes only the user's view and does not affect the server side

Operating System Concepts – 10th Edition

15.2

NFS Protocol

- Provides a set of remote procedure calls for remote file operations. The procedures support the following operations:
 - · searching for a file within a directory
 - reading a set of directory entries
 - · manipulating links and directories
 - · accessing file attributes
 - · reading and writing files
- NFS servers are stateless; each request has to provide a full set of arguments (NFS V4 is newer, less used – very different, stateful)
- Modified data must be committed to the server's disk before results are returned to the client (lose advantages of caching)
- The NFS protocol does not provide concurrency-control mechanisms

45.04

- UNIX file-system interface (based on the open, read, write, and close calls, and file descriptors)
- Virtual File System (VFS) layer distinguishes local files from remote ones, and local files are further distinguished according to their filesystem types
 - The VFS activates file-system-specific operations to handle local requests according to their file-system types
 - · Calls the NFS protocol procedures for remote requests
- NFS service layer bottom layer of the architecture
 - · Implements the NFS protocol

4

NFS Path-Name Translation

- Performed by breaking the path into component names and performing a separate NFS lookup call for every pair of component name and directory vnode
- To make lookup faster, a directory name lookup cache on the client's side holds the vnodes for remote directory names

Operating System Concepts – 10th Edition

15.2

NFS Remote Operations

- Nearly one-to-one correspondence between regular UNIX system calls and the NFS protocol RPCs (except opening and closing files)
- NFS adheres to the remote-service paradigm, but employs buffering and caching techniques for the sake of performance
- File-blocks cache when a file is opened, the kernel checks with the remote server whether to fetch or revalidate the cached attributes
 - Cached file blocks are used only if the corresponding cached attributes are up to date
- File-attribute cache the attribute cache is updated whenever new attributes arrive from the server
- Clients do not free delayed-write blocks until the server confirms that the data have been written to disk
